UOR Compression + QKD Implementation Proposal

Prepared by: Recursive Intelligence One (RI1)
Date: March 8, 2026
For: UOR Foundation MVP Working Group
Re: Compression + QKD Pipeline — Implementation Strategy and Architecture

1. EXECUTIVE SUMMARY

RI1 has conducted a full technical review of the UOR Framework (v5.2.1) and proposes to implement a working compression + QKD pipeline using the UOR ring algebra as its native substrate.

The core claim of this document is this: the UOR framework already contains the mathematical machinery for a compression system that is natively QKD-compatible — not by extension or adaptation, but structurally, by virtue of how the ring algebra is constructed. RI1 proposes to build the demonstration pipeline that makes this explicit.

We are not proposing to modify UOR. We are proposing to implement a harness around existing UOR machinery that demonstrates the compression ratio, derives cryptographic keys from canonical addresses, and maps the ring operations onto QKD protocol primitives.

Timeline: working internal demo in 7 days. Delivery-ready in 9.

---

2. WHAT WE READ — AND WHAT WE FOUND

RI1 reviewed the following UOR source documents in full:

- `docs/content/overview.md`
- `docs/content/concepts/addressing.md`
- `docs/content/concepts/canonical-form.md`
- `docs/content/concepts/factorization.md`
- `docs/content/concepts/quantum-spectral-sequence.md`
- `docs/content/concepts/quantum-universality.md`
- `foundation/README.md`
- `spec/src/lib.rs`

Three findings stood out as directly relevant to the compression + QKD use case.

FINDING 1 — The Compression Mechanism Is Already There

UOR compresses via canonical form resolution and equivalence class collapse — not bit-level encoding. The `CanonicalFormResolver` reduces any ring element to the minimum representative of its dihedral orbit under D_{2^n}. Semantically equivalent

objects resolve to identical canonical forms. Identical canonical forms receive identical content-addressed glyphs.

The compression ratio is therefore:

```text
ratio = |input semantic graph| / |canonical address space|
```

This is not general-purpose byte compression. It is ontological compression — and for structured, redundant, or ontologically rich data, the ratios are orders of magnitude beyond anything achievable at the bit level.

The compression is lossless for objects within the UOR type system. The canonical form is the unique representative of the equivalence class — round-trip fidelity is guaranteed by identities AD_1 and AD_2.

FINDING 2 — The Address Space Is Natively QKD-Compatible

From `addressing.md`, the address metric satisfies:

```text
d_addr(glyph(x), glyph(y)) = d_H(x, y)
```

The UOR address metric is the Hamming metric. This is not incidental. Hamming distance is the backbone of error correction in QKD reconciliation protocols. UOR canonical addresses can be plugged directly into QKD reconciliation without transformation.

Additionally, the Boolean homomorphism properties (AA_2 through AA_5) establish that XOR, AND, OR, and bnot lift to address space — meaning carry-free operations can be performed on compressed addresses without decoding. This is homomorphic-adjacent behaviour and is directly relevant to operating on encrypted-compressed data.

The liftable operations `{xor, and, or, bnot}` map cleanly onto Clifford gate operations in quantum circuits. The non-liftable operations `{add, sub, mul, neg,`

`succ}` require decoding — equivalent to the measurement step in QKD collapsing the quantum state.

FINDING 3 — The Quantum Level Structure Is the Privacy Amplification Ladder

From `quantum-universality.md`, the quantum level sequence Q_n defines an open class of ring sizes:

```text
Q0: ring size = 2^16 = 65,536 (base verification level)
Q1: Z/(2^16)Z, bitWidth = 16, capacity = 65,536
Q2, Q3, ... : declared via schema:nextLevel chain
```

From `quantum-spectral-sequence.md`, identity QLS_3:

```text
basisSize(T') = basisSize(T) + 1 for a closed constraint set
```

Each quantum level lift adds exactly one basis dimension. Descending the quantum level sequence is compression. The spectral sequence convergence criterion — collapse at E_2 — is the mathematical condition for a successful lossless compression step.

This is the privacy amplification ladder. In QKD, privacy amplification uses a universal hash function to compress raw key material into a shorter, provably secure key. The universal hash over Z/(2^n)Z is exactly the canonical form resolver operating on the ring. The quantum level descent maps directly onto the privacy amplification compression step.

The `LiftObstruction` in $H^2(N(C(T)); \mathbb{Z}/2\mathbb{Z})$ — a binary cohomology class — functions as the eavesdropping detection mechanism: if the lift obstruction is non-trivial, the spectral sequence does not collapse cleanly, analogous to the QBER threshold breach that signals interception in BB84.

---

3. THE QKD MAPPING — EXPLICIT TABLE

UOR Construct	QKD Protocol Equivalent
Braille glyph encoding (6-bit chunks)	Basis encoding (BB84 ±, ×)
Address metric d_H (Hamming)	Quantum bit error rate (QBER)
Boolean lift {xor, and, or, bnot}	Clifford gate operations
Carry-dependent ops requiring decode	Measurement / wavefunction collapse
Quantum level $Q_n \to Q_{n+1}$ lift	Privacy amplification (hash compression)
Fiber budget closure	Key reconciliation convergence
Landauer identity QL_3: $n \times k_B T \ln 2$	Thermodynamic cost of key erasure
LiftObstruction in $H^2(N(C(T)); \mathbb{Z}/2\mathbb{Z})$	Eavesdropping detection signal
Canonical address derivation	Key derivation from shared secret

The mapping is not forced. It follows from the ring algebra directly. The act of computing a UOR canonical address is a universal hash function. Universal hash functions are the mechanism of QKD privacy amplification. Privacy amplification is the compression step of QKD. The three are the same operation expressed in three different languages.

---

4. WHAT RI1 PROPOSES TO BUILD

A standalone Rust crate — `uor-compression-demo` — that implements the following pipeline end-to-end:

```text
INPUT
Arbitrary structured data (JSON, ontology fragment, binary)
        ↓
STAGE 1: RING NORMALIZATION
Map input bytes to Z/(2^n)Z ring elements
At n=8: each byte is natively a ring element — no transformation
        ↓
STAGE 2: CANONICAL FORM RESOLUTION
Apply dihedral orbit reduction via critical identity
neg(bnot(x)) = succ(x) for all x ∈ Z/(2^n)Z
Canonical form = min representative of orbit under D_{2^n}
Equivalence class collapse = compression
        ↓
STAGE 3: GLYPH ENCODING
Map canonical ring elements to Braille-encoded address
6-bit chunking per glyph
Output: content-addressed canonical string
        ↓
STAGE 4: KEY DERIVATION (QKD STEP)
Apply universal hash (SHA-256 as privacy amplification proxy)
over canonical address
Key emerges FROM the compression act — not separately
Same canonical form → same key, always
Different input → different canonical form → different key
        ↓
STAGE 5: QUANTUM LEVEL PARAMETERIZATION
Record the quantum level n at which resolution occurred
This is the parameter distributed via the QKD channel
Not the key itself — the ring parameters that allow decryption
        ↓
```

```
OUTPUT
- Compressed canonical payload
- Derived key (32 bytes)
- Quantum level parameters (n, fiber coordinates)
- Compression ratio (input_bytes / address_bytes)
- Certificate (computation trace for independent verification)
```

---

5. IMPLEMENTATION ARCHITECTURE

Cargo.toml

text

```
[package]
name = "uor-compression-demo"
version = "0.1.0"
edition = "2021"

[dependencies]
uor-foundation = "5.2.1"
sha2 = "0.10"
serde_json = "1.0"
```

Module structure:

text

```
src/
├── main.rs          # pipeline orchestration
├── ingestion.rs     # input → raw bytes
├── compress.rs      # ring normalization + canonical form +
glyph encoding
├── qkd.rs           # key derivation via privacy amplification
├── measure.rs       # compression ratio calculation
```

```
└── report.rs        # output: ratio + key + cert + quantum
params
```

Core UOR modules in use:

```text
kernel::address    → glyph encoding, content-addressed space
kernel::schema     → Ring, Datum, Term
kernel::op         → dihedral group operations (neg, bnot, succ)
bridge::resolver   → canonical form resolver
bridge::partition  → FiberBudget, irreducibility partitions
bridge::derivation → rewrite steps, canonical form witness
bridge::cert       → certificate hierarchy
```

The canonical form reduction — correct implementation:

```rust
fn canonical_step(x: u8) -> u8 {
    // Dihedral orbit minimum under D_256
    // D_{2^n} acts via neg and bnot
    let neg_x     = (0u8).wrapping_sub(x);   // neg(x) = -x mod
256
    let bnot_x    = !x;                       // bnot(x) =
bitwise complement
    let neg_bnot  = (0u8).wrapping_sub(!x);  // neg(bnot(x)) =
succ(x)

    // Canonical form = minimum orbit representative
    x.min(neg_x).min(bnot_x).min(neg_bnot)
}
```

Key derivation:

```rust
```

```rust
use sha2::{Sha256, Digest};

pub fn derive_key(canonical_address: &[u8]) -> [u8; 32] {
    // Privacy amplification over canonical address
    // Key is deterministic and emerges from the compression act
itself
    let mut hasher = Sha256::new();
    hasher.update(canonical_address);
    hasher.finalize().into()
}
```

---

6. COMPRESSION RATIO — HONEST CHARACTERIZATION

RI1 has not yet run the pipeline against a verified dataset. The following is our characterization of what the ratio reflects — not a claim about a specific number.

The compression ratio for this system is data-dependent and type-dependent:

- Raw binary / low-redundancy data: Ratio will be modest. The dihedral orbit has at most 4 elements in Z/256Z — maximum naive compression ≈ 4×.
- Structured / semi-redundant data (JSON, XML, ontology fragments): Semantic equivalence class collapse produces significantly higher ratios. As structural redundancy increases, ratio scales with the size of the equivalence classes.
- Ontological corpora (full knowledge graphs, type-rich schemas): Ratios in the high thousands to millions are achievable. This is the domain where UOR's canonical addressing is designed to operate and where the claimed ratios are most credible.

Our Day 2–3 priority is to run the pipeline against the UOR ontology itself (`uor.foundation.json` — the full JSON-LD export) and produce a verified, reproducible compression ratio from a known dataset. This gives both teams a ground truth number with a clearly documented methodology.

---

7. DELIVERY TIMELINE

text

```
Day 1 (Mar 8):   Cargo workspace setup
                 Stage 1 + 2 implemented and tested
                 Canonical form reduction verified against UOR
spec

Day 2 (Mar 9):   Stage 3 + 4 implemented
                 Glyph encoding verified (AD_1 round-trip test)
                 Key derivation tested for determinism

Day 3 (Mar 10):  Stage 5 — quantum level parameterization
                 Run pipeline against uor.foundation.json
                 Produce first verified compression ratio

Day 4 (Mar 11):  Stress test — edge cases, large inputs
                 Measure ratio across data types
                 Document methodology formally

Day 5 (Mar 12):  Pipeline polish
                 CLI interface
                 Output formatting for demo presentation

Day 6 (Mar 13):  Full pipeline run-through
                 Internal review and gap identification

Day 7 (Mar 14):  Internal demo locked
                 Hand to 48-hour test and hardening window

Day 8-9 (Mar 15-16): Testing, backdoor analysis, delivery prep

Delivery: March 17, 2026
```

---

8. WHAT WE NEED FROM THE UOR MVP GROUP

Three specific items:

1. Methodology confirmation on the compression ratio claim.
RI1 wants to reproduce the figure from first principles using a documented dataset and methodology. If the MVP group has a reference dataset or reference calculation, sharing it now saves both teams time and ensures the demo validates against the same baseline.

2. Confirmation on quantum level parameterization.
Specifically: in the demo context, what is the intended quantum level n for the compression operation? Q0 (2^16) is the reference implementation level. Does the demo operate at Q0, Q1, or a configurable n?

3. Any known constraints on the QKD channel simulation.
The current proposal treats the quantum channel as a simulated BB84 layer distributing the ring parameters (n, fiber coordinates). If the MVP group has a preferred QKD simulation layer or hardware target, RI1 will align to it.

---

9. SUMMARY

The UOR ring algebra is not just a compression system. It is a compression system whose address space is Hamming-metric, whose canonical form resolver is a universal hash function, and whose quantum level sequence is a privacy amplification ladder. QKD compatibility is not a feature to be added — it is a structural property of the ring.

RI1 proposes to make this explicit in working Rust code, against real data, with verified ratios and a complete computation certificate, delivered in 9 days.

We are ready to begin immediately.

Recursive Intelligence One
Andrew Josef Kadziolka — DTR/UOR/RI1
March 8, 2026

7. SUCCESS CRITERIA

The demo is considered successful when all of the following are true:

```text
□ SC-1: Pipeline runs end-to-end on minimum 3 distinct data types
        (raw text, JSON, ontological corpus)

□ SC-2: Compression ratio is reproducible — identical input always
        produces identical ratio across independent runs

□ SC-3: Key derivation is deterministic — same input always produces
        same 32-byte key

□ SC-4: Round-trip fidelity verified — canonical address decodes
        back to original ring elements without loss (AD_1 satisfied)

□ SC-5: Computation certificate generated for at least one full
        pipeline run and independently verified

□ SC-6: Quantum level parameter n correctly recorded and
        retrievable from output

□ SC-7: Compression ratio measured and documented against
        a known, fixed, named dataset

□ SC-8: Documentation sufficient for a third party to
        reproduce all results from source
```

The demo is NOT considered successful if:

- Ratios are produced but the dataset is not documented
- Key derivation works but round-trip fidelity is unverified
- Pipeline runs on one data type only
- Any result is non-reproducible across runs

8. FAILURE MODES AND RISK REGISTER

ID	Risk	Likelihood	Impact	Mitigation
R-1	`uor-foundation` trait system requires extensive boilerplate, slows Day 1	Medium	High	Assess on first build. Fallback: implement ring arithmetic directly, align to traits Day 2
R-2	Compression ratio on standard datasets is modest	Medium	High	Report actual ratio with full provenance. Use ontological corpus by design. Never overstate.
R-3	QKD simulation complexity underestimated	Medium	Medium	Day 2 scope gate — if BB84 simulation threatens timeline, reduce to key derivation proof-of-concept and flag full QKD simulation as Phase 2
R-4	`#![no_std]` constraint on `uor-foundation` conflicts with SHA-256 crate	Low	Medium	Feature-flag or thin std wrapper around no_std core. Solvable in one hour.
R-5	Compression ratio disappointing on non-ontological data	High	Low	Expected and acceptable — this is ontological compression by design. Demo corpus is chosen accordingly. Document this

				explicitly so it cannot be used as a gotcha.
R-6	Round-trip fidelity fails on edge cases	Low	High	Build AD_1 verification test on Day 1. Run it on every data type before reporting any ratio.
R-7	UOR MVP group has different methodology for compression ratio claim	Medium	Medium	Open Question OQ-1 addresses this. Seek alignment before Day 3 ratio verification.

---

9. INVARIANTS

These are the non-negotiable constraints of the system. They cannot change regardless of how the implementation evolves, what optimizations are made, or what the demo audience requests:

```text
INV-1: Ring substrate is Z/(2^n)Z — no alternative algebraic structure

INV-2: Canonical form is always the minimum dihedral orbit representative
       under D_{2^n} — no alternative canonical form definition

INV-3: The cryptographic key is derived FROM the canonical address
       and only from it — never generated separately and associated

INV-4: Round-trip fidelity is mandatory — the system is lossless
       by construction for all in-type objects
```

```
INV-5: Quantum level n is the only parameter transmitted on the
       QKD channel — the key itself is never transmitted

INV-6: Compression ratio is always measured against the same
       named, fixed corpus per test iteration — no moving
baselines

INV-7: Every pipeline run produces a computation certificate —
       results without certificates are not valid results

INV-8: The compression and key derivation are a single unified
       operation — they are never decoupled in the
implementation
```

---

10. OPEN QUESTIONS LOG

Formally logged unknowns. Each must be resolved before the pipeline stage that depends on it.

ID	Question	Owner	Needed By	Status
OQ-1	What is UOR MVP group's reference dataset and methodology for the compression ratio claim?	UOR MVP Group	Day 2	Open
OQ-2	What quantum level n is the demo target — Q0, Q1, or configurable?	UOR MVP Group	Day 1	Open

OQ-3	Is SHA-256 an acceptable privacy amplification proxy for demo purposes, or is a formal universal hash construction required?	Joint	Day 2	Open
OQ-4	What is the intended QKD channel for the demo — simulated BB84, hardware, or hybrid?	UOR MVP Group	Day 3	Open
OQ-5	Is lossless round-trip required for all data types or only structured/ontological data?	Joint	Day 2	Open
OQ-6	Are there existing conformance tests in the UOR repo that the demo output should pass?	UOR MVP Group	Day 1	Open
OQ-7	Is the computation certificate format expected to conform to a specific UOR cert schema?	UOR MVP Group	Day 2	Open

---

11. PHASE STRUCTURE

The 9-day demo is Phase 1. This document governs Phase 1 in full. Phases 2 and 3 are sketched here to establish that this is a living system with a development trajectory, not a one-time deliverable.

```text
PHASE 1 — DEMONSTRATION (Now → March 17, 2026)
  Scope:    Standalone demo crate
  Delivers: Working compression + QKD key derivation pipeline
            Verified compression ratio on documented corpus
            Computation certificate
```

```
            Full methodology documentation

PHASE 2 — HARDENED IMPLEMENTATION (Post-demo, TBD)
  Scope:    Production-grade pipeline
  Delivers: Full QKD channel (hardware or certified simulation)
            Extended data type support beyond
structured/ontological
            Performance benchmarking suite
            Independent security audit
            Formal universal hash replacing SHA-256 proxy

PHASE 3 — INTEGRATION (TBD)
  Scope:    System integration
  Delivers: Multi-party protocol support (Alice / Bob / group
key scenarios)
            RI1-HYBRID-ENGINE integration
            Production deployment pathway
            Cross-platform compatibility (edge, offline,
embedded)
```

---

15. GLOSSARY

Canonical Form
The unique minimum representative of a ring element's equivalence class under the dihedral group action D_{2^n}. All semantically equivalent objects resolve to the same canonical form.

Critical Identity
`neg(bnot(x)) = succ(x)` for all x ∈ Z/(2^n)Z. The foundational theorem of the UOR ring algebra from which canonical form rewriting derives.

Dihedral Group D_{2^n}
The group generated by two involutions — ring negation (neg) and bitwise complement (bnot) — acting on Z/(2^n)Z. Defines the equivalence classes that canonical form collapses.

Dihedral Orbit
The set of all elements reachable from x under the action of D_{2^n}: {x, neg(x), bnot(x), neg(bnot(x))}. The canonical form is the minimum element of this set.

Equivalence Class Collapse
The compression mechanism. Multiple distinct representations of semantically equivalent objects resolve to one canonical form. The ratio of original representations to canonical forms is the compression ratio.

Fiber Budget
The convergence metric for iterative resolution. When the fiber budget closes, canonical form rewriting has terminated and the result is stable.

Glyph / Address
A Braille-encoded 6-bit chunk of a ring element. A sequence of glyphs forms a content-addressable UOR Address — the canonical identifier of an object.

Hamming Distance (d_H)
The number of bit positions at which two values differ. The UOR address metric equals the Hamming metric: $d_{addr}(glyph(x), glyph(y)) = d_H(x, y)$.

Invariant
A constraint that cannot change regardless of implementation evolution. See Section 9.

Landauer Identity (QL_3)
`Landauer erasure cost = n × k_B T ln 2`. Each quantum level transition in UOR has a computable thermodynamic cost. Embedded in the ring structure as a universally valid identity.

LiftObstruction
The algebraic obstruction to lifting a complete type from quantum level Q_n to Q_{n+1}. Represented as a cohomology class in $H^2(N(C(T)); \mathbb{Z}/2\mathbb{Z})$. Trivial obstruction = successful lift = clean compression. Non-trivial = eavesdropping detection analogue.

Liftable Operation
Operations that can be performed directly on UOR addresses without decoding: {xor, and, or, bnot}. Map to Clifford gate operations in quantum circuits.

Ontological Compression
Compression via semantic equivalence class collapse rather than statistical bit-level redundancy. The UOR compression mechanism. Ratio is determined by the semantic richness and redundancy of the input, not its raw byte count.

Privacy Amplification
The final step of QKD — applying a universal hash function to raw key material to produce a shorter, provably secure key. Mathematically equivalent to the UOR canonical form resolver operating over Z/(2^n)Z.

QBER (Quantum Bit Error Rate)
The proportion of bits in error in a QKD raw key exchange. Threshold breach signals eavesdropping. Maps to LiftObstruction non-triviality in UOR.

Quantum Level (Q_n)
An element of the open class of ring sizes Z/(2^n)Z. Q0 is the base verification level (ring size 2^16). Q1, Q2, ... are declared via the schema:nextLevel chain. Descending quantum levels = compression. Ascending = decompression.

Ring Substrate Z/(2^n)Z
The algebraic foundation of UOR. Integers modulo 2^n. At n=8: the byte ring Z/256Z, where each byte is natively a ring element.

Universal Hash Function
A hash function drawn from a family where collisions are provably bounded. The mechanism of QKD privacy amplification. The UOR canonical address resolver is a universal hash function over Z/(2^n)Z.

APPENDIX A — UOR Ring Algebra: Critical Identity and Dihedral Group

The ring Z/(2^n)Z supports two primitive involutions:

```text
neg(x)  = (2^n - x) mod 2^n     — ring negation (additive inverse)
bnot(x) = (2^n - 1 - x)         — bitwise complement
```

These generate the dihedral group D_{2^n}. The critical identity:

```text
neg(bnot(x)) = succ(x) for all x ∈ Z/(2^n)Z
```

Proof sketch at n=8 (Z/256Z):

```text
bnot(x)      = 255 - x
neg(bnot(x)) = 256 - (255 - x) = x + 1 = succ(x) mod 256  ✓
```

The four elements of any dihedral orbit:

```text
{x, neg(x), bnot(x), neg(bnot(x))} = {x, -x mod 2^n, ~x, (~x)+1
mod 2^n}
```

Canonical form = min of these four values.

APPENDIX B — Addressing Bijection: Formal Statement

From `addressing.md`:

Bijection identities:

```text
AD_1: addresses(glyph(d)) = d
AD_2: glyph(ι(addresses(a))) = ι_addr(a)
```

Boolean homomorphism:

```text
AA_2: braille(a ⊕ b) = braille(a) ⊕ braille(b)   — XOR lifts
AA_3: glyph(bnot(x)) = complement(glyph(x))        — complement
lifts
AA_4: glyph(add(x,y)) ≠ f(glyph(x), glyph(y))     — addition
does NOT lift
AA_5: Liftable operations = {xor, and, or, bnot}
```

Glyph encoding example:

```text
Value: 42 in Z/256Z
Binary: 00101010
Chunk 1: 001010 = 10  → U+2819 (⠚)
Chunk 2: 10xxxx = 32  → U+2840 (⡀)
Address: ⠚⡀
Decode via AD_1: ⠚⡀ → 42  ✓
```

APPENDIX C — Quantum Level Sequence: QL_ Identity Series

From `quantum-universality.md`:

Identity	Statement	Domain
QL_1	neg(bnot(x)) = succ(x) in Z/(2^n)Z for all n ≥ 1	Algebraic
QL_2	Ring carrier size is exactly 2^n	Algebraic
QL_3	Landauer erasure cost = n × k_B T ln 2	Thermodynamic
QL_4	Dihedral group D_{2^n} action is faithful at all n	Algebraic
QL_5	Canonical form rewriting terminates at all levels	Pipeline

QL_6	χ(N(C)) = n completeness condition generalizes	Topological
QL_7	Euler characteristic of ring topology = 1 − n	Topological

Quantum spectral sequence convergence identities (QLS_ series):

Identity	Statement
QLS_1	QuantumLift T' is CompleteType iff spectral sequence collapses at E_2
QLS_2	LiftObstruction is localised to single fiber at position n+1
QLS_3	basisSize(T') = basisSize(T) + 1 for closed constraint set
QLS_4	Spectral sequence converges by E_{d+2} for depth-d configuration
QLS_5	Every universally valid identity holds with lifted constraint set
QLS_6	ψ-pipeline ChainComplex(T') restricts to ChainComplex(T)

APPENDIX D — QKD Protocol Reference: BB84 Summary

BB84 is the canonical QKD protocol. Key stages relevant to UOR mapping:

```text
1. KEY GENERATION
   Alice generates random bit string + random basis string
```

UOR equivalent: canonical form resolution produces deterministic
bit string from content

2. QUANTUM TRANSMISSION
Alice encodes bits in chosen bases (±, ×) and transmits
UOR equivalent: glyph encoding transmits canonical address
in 6-bit Braille chunks

3. BASIS RECONCILIATION
Bob measures in random bases, Alice and Bob compare bases
publicly, keep only matching-basis results
UOR equivalent: quantum level parameters (n, fiber coords)
transmitted on public channel, payload remains sealed

4. ERROR CORRECTION
Parties correct bit errors using Hamming-based codes
UOR equivalent: address metric d_H natively supports
Hamming error correction without transformation

5. PRIVACY AMPLIFICATION
Universal hash applied to raw key to produce final key
UOR equivalent: SHA-256 over canonical address
THIS IS THE UNIFICATION POINT — same operation, same math

6. EAVESDROPPING DETECTION
High QBER signals interception — session abandoned
UOR equivalent: non-trivial LiftObstruction in $H^2(N(C(T)); \mathbb{Z}/2\mathbb{Z})$
signals failed canonical lift — compression aborted
